Appendix III "Listing of all located events"	24

Introduction

This report is a summary of the arrival times of regional and local earthquakes and located earthquakes in the Basin and Range province and the adjacent areas of Chihuahua, Mexico from January-1976 to August 1980 at the UT/NASA seismic array. The seismicity of the area and details of the UT/NASA array have been previously described by Dumas (to be published in 1981). Therefore the reader should refer to these for details of the array and the methods used in the hypocenter locations. Also, a listing of all published works derived from the UT/NASA array data is given in Appendix I.

Figure 1. Seismicity map of the Basin and Range province and the adjacent area of Mexico. The stations are indicated by triangles (Δ) and locations and abbreviations are given in Table 1. Crosses (+) indicate epicenters located (Appendix III) by the five-station seismic array. Epicenters located by the USGS are indicated by solid squares (\blacksquare) and open circles (o) indicate epicenters located by the ISC. Abbreviations for structural features are: BG-Black Gap Area, DM-Davis Mountains, DP-Diablo Plateau, MB-Marfa Basin, RR-Rim Rock Fault, SB-Salt Basin Graben, and WM-Wylie Mountains. The dashed line marks Muehlberger's (1979) proposed eastern boundary of Basin and Range faulting. Earthquakes with the same epicenter are indicated by (M). The town of Valentine (V) is indicated by the small open square (\square).

Appendix II

Arrival times for local and regional earthquakes ($S-P < 30$ sec)
recorded at station MOT from January 1976 to August 1980.

Appendix III

Instrumental locations for earthquakes in the Basin and Range province of Texas and the adjacent area of Mexico. Locations were determined by the use of HYPO-71 (Lee and Lahr, 1975). The column headings are as follows:

Date - Year/month/day

Origin Time - This is universal time (UT) and is given to the nearest tenth of a second.

Lat N - Latitude (North) given to the nearest hundredth of a minute.

Long W - Longitude (West) given to the nearest hundredth of a minute.

Depth - Depth is given in km. (*) indicates depth is constrained to 4 km.

Mag - The magnitudes listed are local magnitudes determined from signal durations and are obtained from the following formula (Dumas, In preparation)

$$m_1 = 2.1 \log t - 2.51$$

MOT, BP, EM, MR, and BR - These are the UT/NASA stations used in the location scheme. The numbers in the columns indicate the number of readings used to locate each event per station. One (1) indicates P-wave arrival only and two (2) indicate both P and S wave arrivals were used.

Dmin - Distance to nearest station in km.

Gap - Largest azimuthal separation in degrees between stations.

RMS - Root mean square error of time residuals in sec.

ERH - Estimated standard error of the epicenter in km. If ERH is blank this means ERH cannot be computed because of insufficient data.

ERZ - Estimated standard error of the focal depth. If ERZ is blank this means that ERZ cannot be computed because either the focal depth was fixed in the solution or because of insufficient data.

Q - Quality of the hypocenter solution. This measure is intended to indicate the general reliability of the solution (Lee and Lahr, 1975).

Comments - The three (3) letter code indicate additional station(s) used in the epicenter locations.

ACKNOWLEDGMENTS

I thank Messrs. John Reynolds, Albert Fay, Clay Miller, and James E. White Jr., for permitting us to place our remote seismic stations on their ranches. The cooperation of Mr. Jess Sorrels, manager of the X Ranch, and Mr. John Herrin, manager of the Eagle Mountain Ranch, is also greatly appreciated. I thank Mr. Curtis Laughlin, superintendent of McDonald Observatory, for his generous cooperation, and Mr. Robert Gonzales and Mr. Windell Williams for their invaluable help in operating and maintaining the central station equipment at McDonald Observatory. I would especially like to thank Mr. L. Pakiser and the U.S. Geological Survey for providing much of my personal financial support while undertaking this study. I thank C.A. Frohlich for providing an epicenter location program, along with the Herrin travel-time tables, also for critically reviewing the manuscript and for helpful comments. I am indebted to W.R. Muehlberger who pointed out that Sellards' intensity data are consistent with other information on the strike of the Valentine Fault and for other useful comments. A.R. Sanford and O. Nuttli gave helpful reviews of the paper (Dumas et al., 1980), upon which Part I is based. I also thank R. Buffler and D. McCowan for reviewing the manuscript and for their helpful comments. I thank Drs. B.A. Bolt and R. Uhrhammer for allowing us to examine Byerly's collection of seismograms of the Valentine earthquake. I also thank Drs. J. Dorman and G. Latham for their constant advice and guidance in writing this manuscript.

The West Texas network program was supported by the National Aeronautics and Space Administration Grant NSG-7159.

SEISMICITY OF WEST TEXAS

Publication No.

David Byron Dumas, Ph.D.
The University of Texas at Dallas, 1981

Supervising Professor: H. James Dorman

A four year seismic study has found the Basin and Range province of west Texas and the adjacent area of Mexico to be more seismically active than heretofore known. A University of Texas five station seismic array around the Marfa Basin has located or detected approximately 800 local and regional earthquakes with S-P times of less than 30 sec.

A crustal model for the Basin and Range is derived from natural and artificial sources and contains four layers having velocities of 3.60, 4.93, 6.11, and 6.60 km/sec, respectively, overlying a mantle of 8.37 km/sec. A moderate level of seismic activity has been detected near Van Horn, in the Marfa Basin (particular the eastern side), and along the Texas-Mexico border between latitudes 30° and 31° N. Five earthquake sequences were recorded, two near the Texas-Mexico border and three in the Marfa Basin. Four of these sequences showed quiescent periods in foreshock activity preceding the main shock. On the eastern side of the Marfa Basin a diffuse linear seismic zone may represent an unmapped fault, striking $N 50^{\circ}W$ that coincides with Muehlberger's proposed eastern boundary of Basin and Range faulting.

A new epicenter for the Valentine, Texas earthquake of August 16, 1931 has been relocated instrumentally at the northern end of this diffuse

zone. Regional and local teleseismic P-wave arrival time anomalies observed for the nearby Gnome underground nuclear explosion of 1961 are used to determine station corrections and thus to locate the new 1931 epicenter at 30.69°N , 104.57°W . Several estimates of magnitude (m_b) based on intensity data range from 5.6 to 6.4. Fault-plane and composite fault-plane solutions supports Muehlberger's hypothesis that the Basin and Range is undergoing extension in a SW-NE direction.

PART I. A REEVALUATION OF THE AUGUST 16, 1931 TEXAS EARTHQUAKE

INTRODUCTION

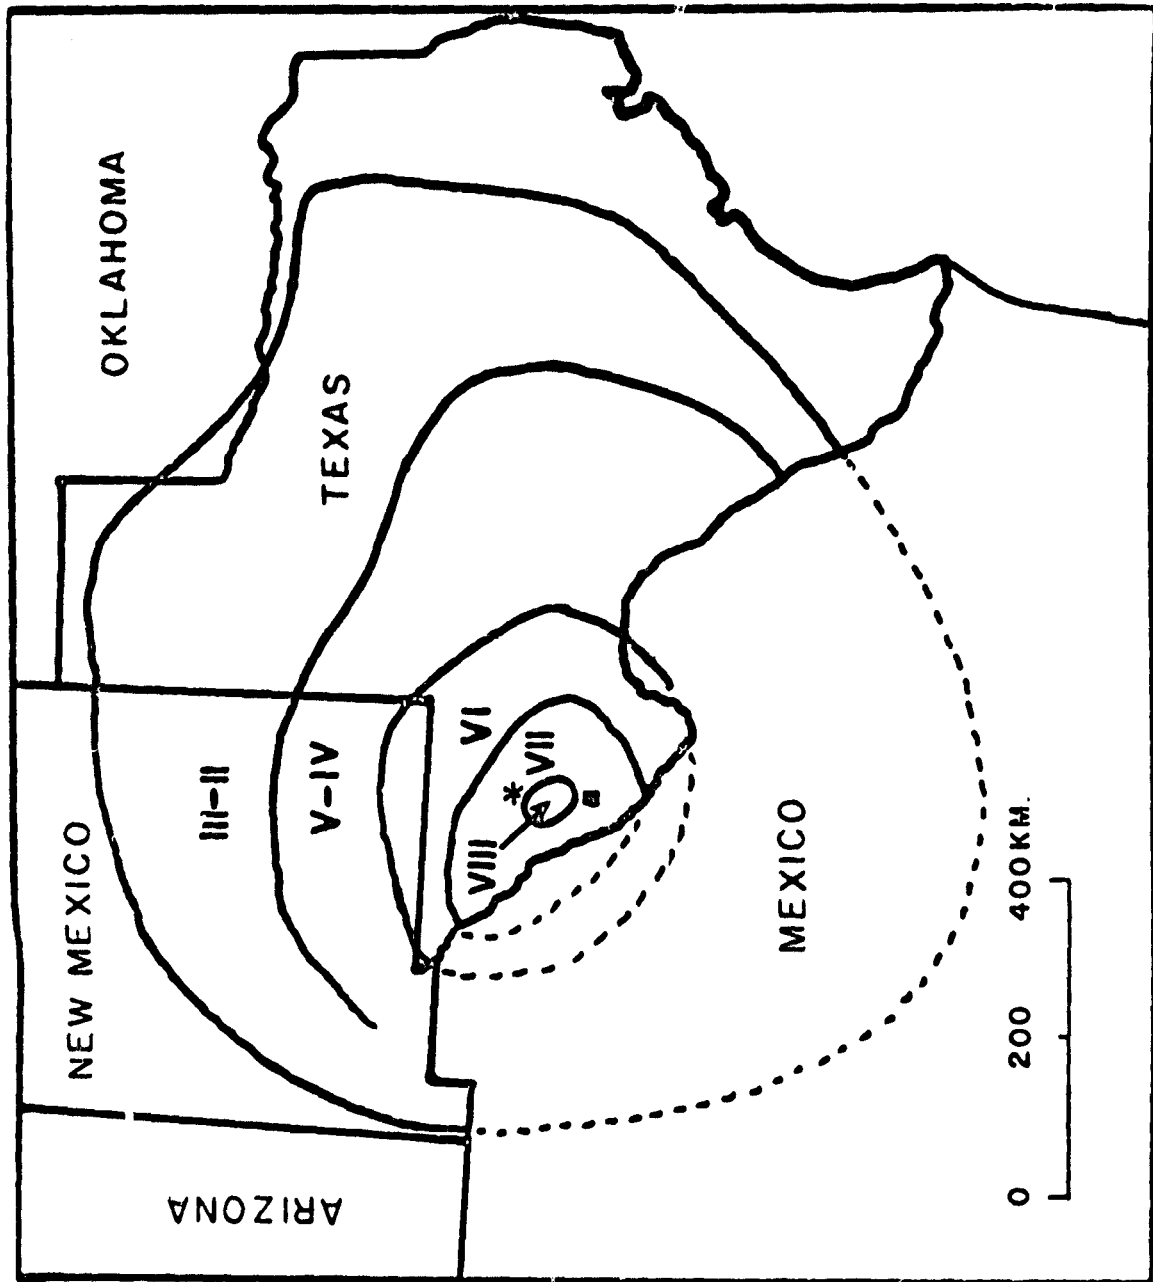

On August 16, 1931, an earthquake occurred in far west Texas near Valentine, which shook most of Texas, New Mexico and the adjacent areas of Mexico. The main shock was preceded by several felt foreshocks and followed by several felt aftershocks which persisted for a period of at least 3 months (Sanford and Topozada, 1974; Sellards, 1932). This event is said to have been the largest historic earthquake in Texas (von Hake, 1977).

Two instrumental locations and origin times have been published for this earthquake. The USCGS placed the epicenter at 29.90°N and 104.20°W , and the origin time at 11 hr 40 min 15 sec (UTC) (United States Earthquakes, 1931). Byerly (1934a and b) made a detailed investigation of the teleseismic travel times of this earthquake. By placing the arrival times of the nine nearest stations on a straight line, he found the epicenter to be 30.88°N and 104.18°W and the origin time to be 11 hr 40 min 21 sec. The problem posed by these contemporary reports is that both epicenters fall outside the area of maximum intensity (Figure 1). Since no surface breakage was reported from any area (Sellards, 1932), the active fault along which the earthquake occurred remained unidentified and the regional tectonic significance of the Valentine earthquake could not be satisfactorily assessed from the conflicting evidence.

This analysis was stimulated by the work of Herrin and Taggart (1962) who found the instrumentally located epicenter of the Gnome underground nuclear explosion, detonated near Carlsbad, New Mexico, on December 10, 1961, fell 16 km east of the explosion site. It was suggested (Herrin and Taggart, 1962) that this was caused by systematic differences between the velocities

Figure 1: Isoseismal (Rossi-Forel) map for the August 16, 1931 Texas earthquake (redrawn from Sellards, 1932). Byerly's epicenter location is indicated by * and the USCGS epicenter by ■ .

Figure 1

of P_n in the eastern and western United States. A similar offset must be expected regarding Byerly's epicenter for the Texas earthquake since it lies only 160 km south of the Gnome site. This paper utilizes the observed residuals from the Gnome explosion to adjust station corrections and obtains a new epicenter based upon Byerly's arrival-time readings. This epicenter satisfies not only the travel-time data, but also coincides with the observed maximum isoseismal to the Texas earthquake and with the newly discovered active seismic trend near Valentine (See Part II). Thus, the new epicenter is consistent not only with the data of 1931, but also with relevant seismic data that have become available much more recently as well.

REVISED EPICENTER LOCATION

Local and regional P-wave arrival times listed in Table 1 (Byerly, 1934a) were used in a hypocenter location program. These 19 stations were chosen for the following reasons: (1) their Gnome travel-time residuals were available, and (2) the arrivals, as listed by Byerly, were of sufficient amplitude that they could be read with little uncertainty. Denton, Texas was not used in the hypocenter location program because the exact location of the 1931 seismic station could not be obtained. The program utilizes the Herrin earth model (Herrin et al., 1968) to determine hypocentral parameters by minimizing the observed minus the calculated travel-time residuals, in a weighted least-squares sense. The effect of local structure differing from the Herrin model was removed by subtracting from Byerly's readings the Gnome travel-time residuals (Herrin and Taggart, 1962) as listed in the corrections column of Table 1. Travel-time corrections for distant stations outside the conterminous 48 states were made by subtracting the mean travel-time residuals of station MOT (McDonald Observatory in far west Texas) for

earthquakes that are located in the vicinity of these distant stations. This procedure is valid for correcting the distant station data because of the near proximity of MOT and the new Valentine epicenter to the Gnome explosion. The residuals listed in Table 1 are those obtained with respect to the new epicentral solution.

Based on the data listed in Table 1, the new epicenter is 30.69° $N \pm 0.41$, $104.57^{\circ}W \pm 0.30$, the depth is 29.1 ± 25 km, and the origin time is 11 hr 40 min 21.9 ± 2.8 sec. The weighted standard error of the travel-time residuals is 2.85 sec. The standard error associated with the travel-time residuals is large and is typical of the formal uncertainties obtained with early data such as these (Gawthrop, 1978). This reflects the approximation in locations given for many of the older stations and also the less stringent standards of station time-keeping that prevailed in that era. Nevertheless, the revised epicenter location in the Marfa Basin, 42 km southwest of Byerly's epicenter, is closely consistent with the relationship noted between the instrumental and actual epicenters of the Gnome event. The displacement of the earlier epicenter and the azimuth of displacement is also different in the two cases because the azimuthal distributions of stations were different as well.

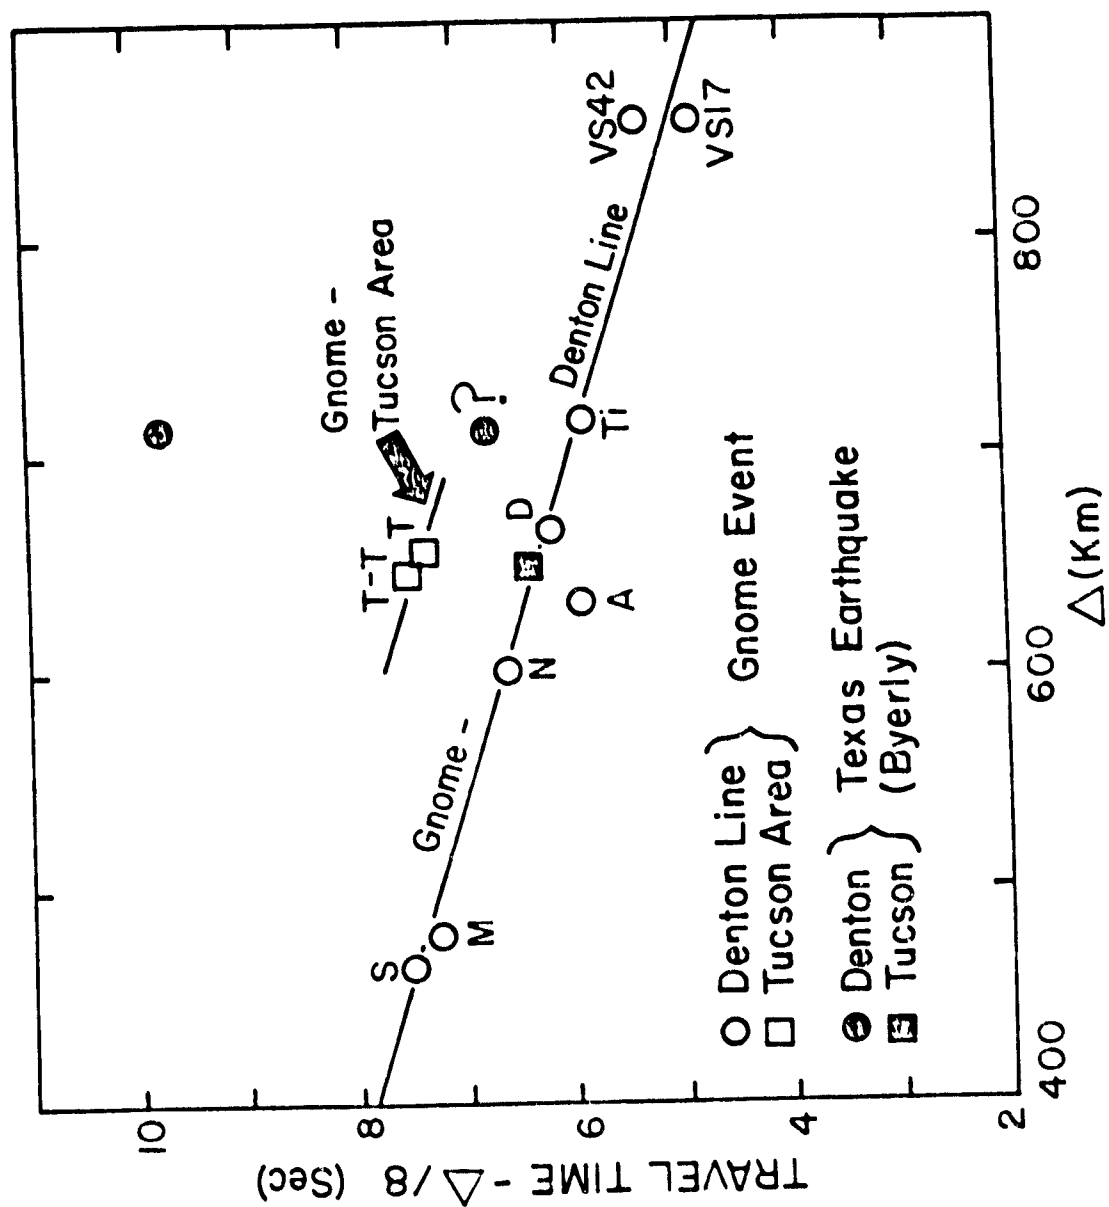

Examining the problem further, the numerical (least squares) equivalent to Byerly's graphical solution for the 1931 epicenter is calculated by fitting his nine closest data points to a single straight line. As expected, the results agrees precisely with Byerly's, since we merely solved the numerical version of Byerly's graphical problem. In this method, a uniform mantle to the east and to the west is implicit in the assumption of a single P_n line.

Gnome results and numerous refraction experiments in the west have shown a strong east-west gradient of mantle velocity across the eastern margin of the Rocky Mountain front and Rio Grande rift in New Mexico. This is reflected in the separation of the Gnome instrumental epicenter and the actual site of the explosion. Therefore, Byerly's closest readings of the Texas earthquake seismograms are compared directly with data of the Gnome explosion (Romney et al., 1962) which occurred at 32.264°N , 103.866°W , only 160 km to the north of Valentine. Byerly's closest observations of the Texas earthquake were TUC (Tucson Observatory), 650 km to the west, and Denton (in this paper Denton will be referred to as DTX), 700 km to the east, while during the Gnome experiment there were two recording points near Tucson, and there was a line of stations which passed near Denton, Texas. Byerly's 1931 readings are plotted as solid symbols in Figure 2, while the Gnome P_n arrivals are plotted as open circles and squares. Clearly, Byerly's Tucson data point would agree better with the Gnome observations if his epicenter were moved 1 sec, or about 8 km, closer to Tucson.

Regarding the Denton data, Byerly's first arrival pick would be aligned with the Gnome-Denton line in Figure 2 if his epicenter were displaced by about an equal distance away from Denton. However, the true distance is probably four times as much, since three reasons are seen for questioning Byerly's (1934b) identification of the first arrival. First, he reported the earliest motion as a trace amplitude of 0.1 mm, while an arrival 3 sec later had an amplitude of 0.9 mm. He also reported 2 mm as the amplitude of first motion at Tucson. In the Gnome experiment, the stations around Denton recorded the largest ground amplitudes anywhere, about three times larger than those of the Tucson stations (Herrin and

Figure 2: Reduced travel-time data for the Gnome explosion of December 10, 1961 (Romney et al., 1962) and the Texas earthquake of August 16, 1931 (Byerly, 1934b) recorded near Denton, Texas and Tucson, Arizona. From left to right, the Gnome recording stations are Seymour, Mabelle, Nocomo, Ardmore, Tucson-T, Dallas, Tishomingo, and Volunteer Stations 17 and 12. The question mark identifies the first Denton arrival of 0.1 mm read by Byerly. The arrival 3 sec later was recorded as 0.9 mm in amplitude.

Figure 2

Taggart, 1962). While the magnification used at Denton and Tucson in 1931 is not known, it seems probable at this time that the first small motion at Denton might have been spurious noise. Having examined the original seismogram read by Byerly (his collected seismograms of this earthquake are stored at Berkeley), his pick seems credible, but it is nearly as small as any feature that could be seen on this seismogram. Thus, it can be regarded as doubtful. Second, the early pick at Denton leaves a very long $\bar{P} - P_n$ interval by comparison with Gnome observations at similar distances. Third, the polarity of the later and stronger arrival is in agreement with other points in the northeast quadrant of the fault-plane solution (Figure 3, DTX), while the earlier arrival is inconsistent on this score. Regarding \bar{P} , it is evident that the phase identified by Romney et al., (1962) on the Gnome records is not the same phase which Byerly called \bar{P} . The present interpretation has allowed for this fact.

Accepting the later pick for Denton, Byerly's epicenter of the Texas earthquake must be moved about 4 sec, or 32 km, away from Denton in order to place the Denton point on the Gnome-Denton line (Figure 2). This, combined with shifting the epicenter 8 km closer to Tucson, moves it southwestward about 35 km. This places the epicenter just north of Valentine, Texas and in the area of maximum seismic intensity (Sellards, 1932). This graphical solution is in excellent agreement with the solution obtained above by recomputation based on 19 first arrivals.

FAULT-PLANE SOLUTION

Using the first-motion readings reported by Byerly (1934a; the Denton, Texas polarity used is opposite that given by Byerly), a new fault-plane solution of the 1931 Texas earthquake was determined. Figure 3 shows

Figure 3: Fault-plane solution (equal area, lower hemisphere projection) for the 1931 earthquake. Closed circles indicate compression. Open circles indicate dilation. The direction of compression and tension axes are marked by P and T, respectively. The Denton, Texas arrival is indicated by the code DTX and the Tacubaya arrival by TAC. Polarities used in this solution are the readings of Byerly (1934a) except for DTX.

Figure 3

an equal area projection of the lower hemisphere of the focal sphere for all arrivals. The nodal planes are

	<u>plane α</u>	<u>plane β</u>
strike	N59°W	N36°E
dip	70°NE	70°SE

The strike of nodal plane β is approximately perpendicular to the trend of the Marfa Basin in which the epicenter falls. Therefore, it seems that nodal plane β is the auxiliary plane, and plane α is the fault plane. Thus, the solution indicates a strike-slip fault with right-lateral displacement. The tension and compression axes trend S74°W and S16°E, respectively. These directions indicate that elongation is occurring in the direction slightly south of west and north of east.

Using the polarity data of Byerly, Sanford and Topozada (1974) obtained a solution indicating normal faulting striking N40°W, dipping 74°SW. Their solution, however, has more inconsistent points than the one represented in Figure 3. Figure 3 has only one gross inconsistency, a point in the southeast quadrant representing the first motion at Tacubaya (TAC). All other inconsistent points are near the the nodal planes.

MAGNITUDE

Several previous authors have estimated the magnitude of the 1931 Texas earthquake. Gutenberg and Richter (1949) gave a value of 6.4. The same value was obtained by Sanford and Topozada (1974) using a method based on the size of the felt area. Nuttli (1976) obtained a magnitude (m_b) of 5.6 using the method of intensity gradient as described in detail by Nuttli (1973, 1976) and Nuttli et al., (1979). I reviewed the application of

Nuttli's method using the intensity data of Figure 1 which is plotted from Rossi-Forel intensities reported by Sellards (1932). Allowing for the difference between the Rossi-Forel and Modified Mercalli scales, one obtains agreement with Nuttli's result by using the spacing of isoseismals (Figure 1) normal to the trend of the valley, which is also normal to the direction of faulting (see fault-plane solution, Figure 3). Parallel to the valley, the spacing of isoseismals is greater, giving a magnitude of 5.9 (m_b) by the same method.

FORESHOCKS

Sellards (1932) mentioned that foreshocks of the 1931 earthquake were recorded at Denton, Texas and St. Louis, Missouri. Another reliable report of foreshocks was obtained from Mrs. York (personal communication) who lives on the western side of the Davis Mountains, about 25 km east of the new epicenter. She stated that she and her family had slept outside their ranch house during most of the preceding night because they felt several shocks hours before the main shock at 05:40 a.m. (local time).

CONCLUSION

A revised location of the Texas earthquake of 1931 places the epicenter at 30.69°N , 104.57°W , on a fault striking $\text{N } 59^{\circ}\text{W}$ and with a right lateral strike-slip mechanism. Discrepancies with other data are thereby resolved since the new location falls within the area of maximum seismic intensities of the 1931 earthquake.

PART II. SEISMICITY AND CRUSTAL STRUCTURE OF THE BASIN AND RANGE PROVINCE OF WEST TEXAS

INTRODUCTION

In the summer of 1975 the University of Texas and the National Aeronautics and Space Administration (UT/NASA) began a long term geophysical program designed to support the geodetic laser ranging measurements from the McDonald Observatory located in the Davis Mountains of Texas. The purpose of the long term program is to maintain surveillance of the regional tectonic processes.

This paper describes the seismological results obtained during a four year period. Epicenters were calculated using a crustal model of the Basin and Range province obtained from natural and man-made seismic sources, including the 1960 Gnome underground nuclear explosion in southeastern New Mexico. When the data permitted, fault-plane and composite fault-plane solutions were also obtained. This study shows that the number of earthquakes recorded in Basin and Range province of west Texas and the adjacent area of Chihuahua, Mexico is greater than previously mentioned. None of the local or regional earthquakes detected or located during this study were located by the United States Geological Survey (USGS) or the International Seismological Centre (ISC).

GENERAL GEOLOGY AND PHYSIOGRAPHY

Trans-Pecos Texas (T-PT) is separated into two physiographic provinces, the Great Plains and Basin and Range provinces. Here the Great Plains province is characterized by a belt of plains and low plateaus, 80-100 km in width, with no major geologic changes within the province. West of the Great Plains in T-PT is a region of mountains and intermontane basins

(Basin and Range province, B&R). A geologic boundary between the northern and southern regions of the B&R is approximated by Interstate Highway 10. In the northern region, the rocks are mainly of Mesozoic and Paleozoic ages, including extensive Permian limestones and dolomites, Cretaceous limestones and sandstones, and a few scattered outcrops of intrusive volcanics (Barker and Hodges, 1977). The region also contains one of the two exposures of Pre-Cambrian rocks in the state.

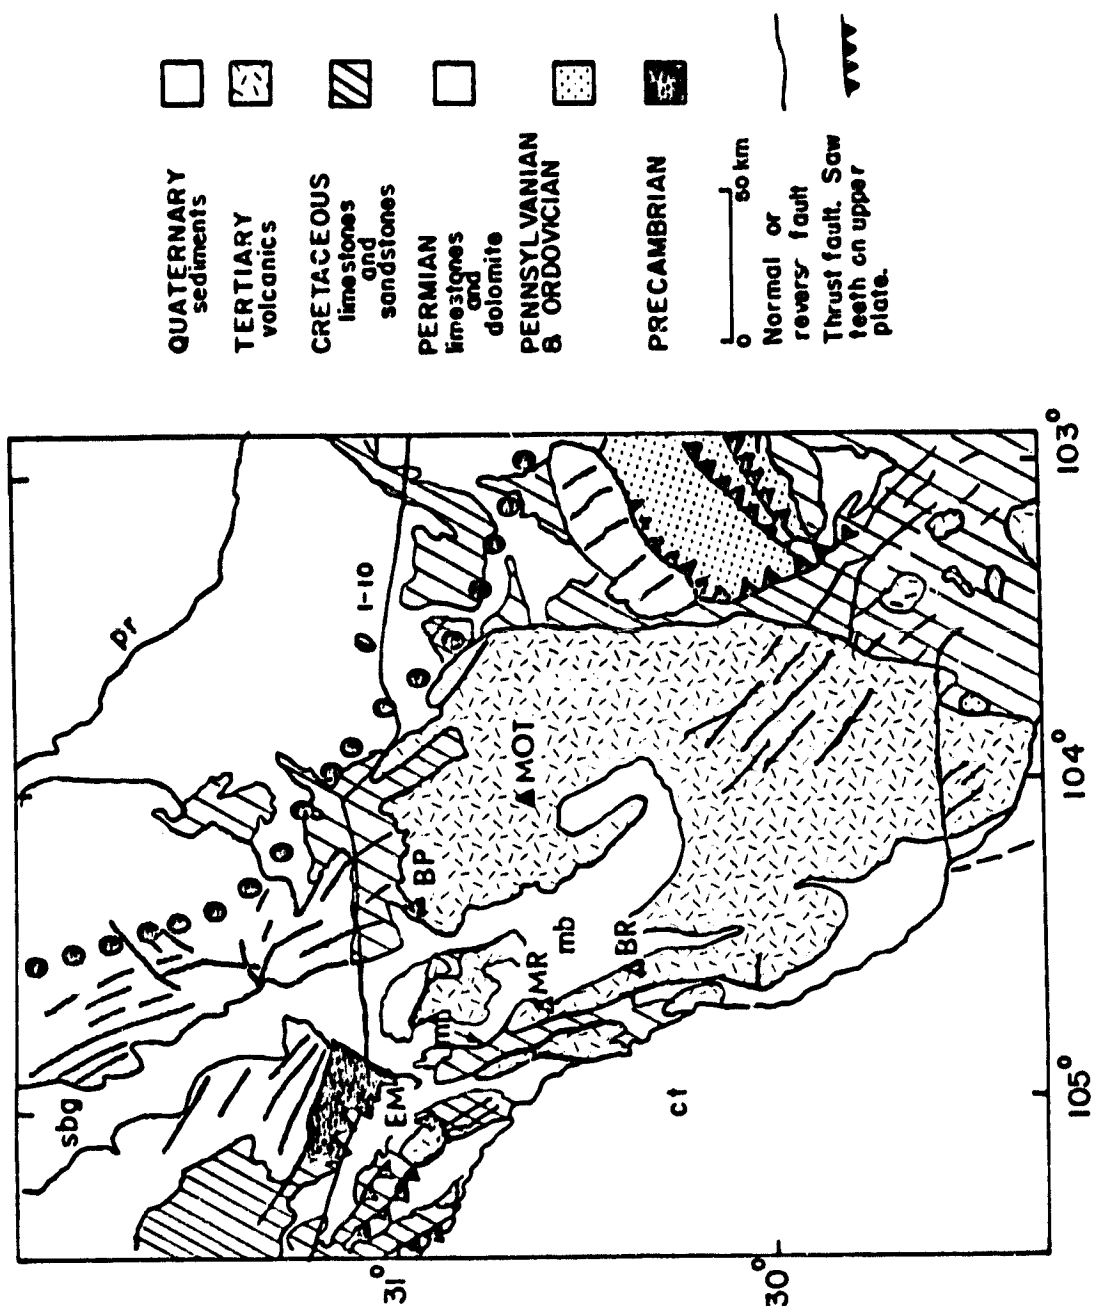

The most prominent structural feature of the northern region is the Salt Basin Graben (Figure 4). The graben is bounded on both sides by extensive Quaternary faults. Faults on the eastern side of the graben are short and widely dispersed; on the western side, the faults are more continuous (Muehlberger, 1978).

In the southern region, the rocks are composed mainly of Tertiary volcanic sequences. The Salt Basin Graben extends southward into the southern region where it is known as the Marfa Basin. The eastern side of the Marfa Basin exhibits very little surface evidence of faulting, but the western side is bounded by numerous normal faults, the most prominent being the Mayfield Fault. Most of the basin fill is composed of unconsolidated Quaternary sediments. Shurbet and Reeves (1977) estimated from gravity measurements basin fill to a depth of at least 2.4 km in the Marfa Basin.

West of the B&R is a narrow northwest-southeast trending structural depression known as the Chihuahua Trough. Sediments which accumulated in the Chihuahua Trough during the late Jurassic and Cretaceous time underwent complex folding and eastward overthrusting with associated tear faults during the Laramide (Gries and Haenggi, 1970).

Figure 4: Geologic map showing major structural features of Trans-Pecos Texas. The dotted line indicates the boundary between the Basin and Range (southwest) and the Great Plains (northeast) provinces (Muehlberger, 1978). Station names and locations (▲) are identified in Table 2. Other abbreviations are: ct - Chihuahua Trough, I-10 - Interstate 10, mb - Marfa Basin, mf - Mayfield Fault, pr - Pecos River, sbg - Salt Basin Graben. (redrawn from the Geological Highway map of Texas).

Figure 4

HISTORICAL SEISMICITY OF WEST TEXAS AND CHIHUAHUA, MEXICO

Though there is evidence of minor seismicity in west Texas and Chihuahua, adequate historical information is lacking due to sparse population and poor instrumental coverage. The first documented earthquake in west Texas occurred near El Paso on March 7, 1923 (Sanford and Topozada, 1974). Several events have since been located or felt in the El Paso area and other areas of T-PT (von Hake, 1977). The largest instrumentally located earthquake in Texas occurred on August 16, 1931 (Byerly, 1933a and Dumas et al., 1980) near the town of Valentine and aftershocks were felt for a period of three months (von Hake, 1977). The most recently felt earthquake in Valentine occurred on August 1, 1975.

Only recently have seismic studies begun to focus on the seismicity of west Texas. Chan (1977), in a three month study of the B&R, located 9 events across T-PT; of which three were located in the B&R. Dumas (1979) has noted an active seismic focus near Snyder, Texas. On June 16, 1978 a magnitude 4.6 earthquake occurred in the Snyder area and this earthquake is the largest event to occur in Texas since the 1931 event. Rogers (1979) suggests that local earthquakes recorded at the Kermit, Texas array in the Permian Basin may be associated with the secondary recovery of hydrocarbons.

In Chihuahua, the first earthquake located instrumentally occurred on September 10, 1963 (Earthquake File Tape, National Earthquake Information Service). Since then at least 15 earthquakes have been located ($m_b > 4.8$) along a diffuse line striking northeasterly across northern Chihuahua.

SEISMIC ARRAY AND INSTRUMENTATION

The UT/NASA seismic array consists of five short-period remote stations (Table 2) located in the B&R of west Texas (Figure 4). The array

Table 2

Station Names, Coordinates, Elevation, and Station Corr.

	Station	Lat.	Long.	Elev(m)	Corr.
MOT	McDonald Observatory	30.68N	104.11W	2080	0.10
BP	(MT1) Boracho Peak	30.93N	104.39W	1720	-0.03
EM	(MT2) Eagle Mountain	30.90N	105.08W	2088	0.10
MR	(MT3) Miller Ranch	30.53N	104.67W	1584	0.06
BR	(MT4) Brite Ranch	30.27N	104.58W	1584	-0.13

encloses an area of about 4000 km^2 , the longest interstation distance is 105.5 km (stations EM and MOT).

Each station consists of a 1 hz vertical-component geophone (Geotech model 18300) situated on bedrock, a pre-amplifier (maximum gain of 104 db), a 5 hz low pass filter, a voltage controlled oscillator, and 0.25 watt radio transmitter. Each remote station is powered by a solar panel charging a 12 volt battery. The seismic signal is transmitted either directly or relayed to the central station at McDonald Observatory. At the central station the seismic signal from each station can be delayed 10, 20 or 40 sec in a digital memory. The selected delay time determines the sampling rate of the analog to digital converter and also determines the cutoff frequency for the low-pass antialiasing filter. For the west Texas network the 40 sec delay ensures the recording of the onsets of all local events for which late arriving phases "trigger" the array. The delayed signal is then recorded along with the WWV time code on an 8 channel Brush strip chart recorder. The recorder runs continuously at a chart speed of 0.01 mm/sec; however, the chart speed is automatically increased to 10 mm/sec when an event is detected at two, three, or more stations within a prescribed time window. Detection occurs when the instantaneous signal exceeds the average background signal by a selectable ratio. The average background signal is obtained by rectifying and smoothing (time constant 120 sec) the output of the seismometer. The system operates at a peak magnification of 250,000 (-12 db) at 6 hz (Figure 5). The output of the MOT seismometer, located 1 km from McDonald Observatory, is also recorded on a helicorder at a speed of 1 mm/sec, thereby ensuring a readable arrival time at MOT for events that are not recorded at 10 mm/sec. Because of the occasional high winds at EM and BP, peak magnification for these stations is limited to 125,000.

Figure 5: Magnification curves for the UT/NASA array and the Wood-Anderson torsion seismometer. The peak magnification of the UT/NASA system is 500,000 (at the -6db amplifier setting) at 6 hz.

Figure 6: Richter local magnitude versus signal duration curve for local events. Magnitudes were determined from equation 1. Signal duration is measured in seconds from the time of first break until the signal amplitude decays to twice the background noise.

Figure 5

Figure 6

MAGNITUDE AND RECURRENCE TIME OF EARTHQUAKES

Local magnitudes (m_L) listed in this paper were obtained by multiplying the trace amplitudes recorded at MOT by the ratio of the standard Wood-Anderson magnification curve to the MOT magnification curve. The definition of the local Richter magnitude then becomes:

$$m_L = \log A + \log (M_{wa}/M_{4-6}) - \log A_0 \quad (1)$$

where A is the peak recorded amplitude in millimeters at MOT, M_{wa} is the magnification of the Wood-Anderson torsion seismometer (2800), M_{4-6} is the mean magnification of the instrument at station MOT between 4 and 6 hz, and A_0 is the amplitude of a magnitude zero earthquake in millimeters, recorded on a Wood-Anderson seismometer, as given by Richter (1958). The mean magnification between 4 and 6 hz (225,000) is used because the largest amplitudes in the seismic traces are in this frequency range. The 4 to 6 hz portion of the MOT magnification curve corresponds to the flat portion (2800) of the Wood-Anderson curve (Figure 5). The middle term on the right hand side of equation 1 is equal to -1.91 and varies by less than 0.1 unit of magnitude for the frequency range between 4 and 6 hz.

The magnitudes obtained from equation 1 are plotted against signal duration (Figure 6) for 28 events, located by this array and the Kermit array. Local magnitude can then be expressed in terms of duration as:

$$m_L = 2.10 \log \tau - 1.52 \quad (0 < \Delta < 210 \text{ km}) \quad (2)$$

$$m_L = 2.10 \log \tau - 1.52 + 0.0009\Delta \quad (\Delta > 210 \text{ km}) \quad (3)$$

where Δ is the epicentral distance (km) to station MOT and τ is the signal

duration measured from the time of the first break (P-wave arrival) to the time when the coda amplitude decays to twice the background noise. A reading error of $\pm 20\%$ in signal duration corresponds to ± 0.2 magnitudes units. The inclusion of additional data in Figure 6 does not significantly alter equations 2 and 3. The distance correction in equation 3 was estimated by subtracting equation 2 from magnitudes listed for regional earthquakes (Earthquake Data Reports, USGS and Rogers, 1979) farther than 210 km from MOT.

The magnitude data used in the frequency-magnitude curve (Figure 7) were determined from equations 2 and 3. Artificial events near Van Horn (Seismicity Section) that may be included in the data have magnitudes less than 1.5. Since these events lie along the flat portion of the frequency-magnitude curve their effects on the slope of the curve is minimal. Rogers (1979), indicated that Kermit events with magnitudes greater than 1.9 may be related to hydro-carbon production and this would alter the slope of the frequency-magnitude curve in Figure 7. The 'b' values were computed by least-squares (LS) and maximum likelihood (ML) (Aki, 1965) methods and are given in equations 4 and 5, respectively:

$$\log N(m_x) = 4.85 - 1.17 \pm 0.03 m_x \quad (4)$$

$$\log N(m_x) = 4.51 - 1.04 \pm 0.11 m_x \quad (5)$$

where $N(m_x)$ is the cumulative number of earthquakes above magnitude 1.9. Both 'b' values are in agreement with Rogers (1979) 'b' values of 1.28 (LS) and 1.04 (ML) for events near Kermit.

Using equations 4 and 5, the probability that in the time interval, (0,T) at least one earthquake of magnitude m_x should occur is given by

Figure 7: Cumulative number versus magnitude curve for all events recorded between January, 1976 and December, 1978 at station MOT ($S-P < 30$ sec). Two 'b' values obtained for the portion of the curve greater than 1.9 are 1.17 and 1.04 by using the least-squares and maximum likelihood methods, respectively.

Figure 7

(Sacuiu and Zorilescu, 1970)

$$P(m_l, T) = 1 - e^{-N(m_l)T/3.0} \quad (6)$$

Since equations 4 and 5 were obtained over a 3.0 year period the exponent is divided by 3.0 to obtain the mean value for one year. Therefore, the mean recurrence period (in years) for an earthquake is

$$T_{\text{mean}} = \frac{3.0}{N(m_l)} \quad (7)$$

The most destructive earthquake to occur in the area had a magnitude estimated to be between 5.6 and 6.4 m_b (The 1931 earthquake). Extrapolating equations 4 and 5 beyond the given range of magnitudes shown in Figure 7 the estimated probability for magnitudes 5.6 and 6.4 earthquakes and their mean recurrence periods are given in Tables 3 and 4. The ML estimate of the mean recurrence based on equation 4 is 61 years for a magnitude 5.6 earthquake.

Although west Texas has been sparsely populated since the mid-19th century (and still is today), it is highly unlikely that a magnitude 5.6 earthquake would go undetected or unreported. The discrepancy between the theoretical recurrence period and the number of earthquakes ($m_b = 5.6$) actually occurring can be attributed to one or all of the following: (a) uncertainty in the 'b' value (ML), (b) differences between the local magnitude scale and body wave magnitudes, (c) temporal changes in seismicity, and (d) the 1931 earthquake was larger than 5.6. The other three mean recurrence periods based on the ML and LS methods for a 5.6 or 6.4 earthquake are large and cannot be verified on a historical basis.

Table 3

Earthquake Risk and Recurrence Rate

T^1	$P(5.6, T)_{LS}^2$	$T(5.6)_{LS}^3$	$P(5.6, T)_{ML}^2$	$T(5.6)_{ML}^3$

CRUSTAL MODELS

Crustal models (Figures 8a and b) for T-PT are derived from the data of untimed quarry blasts, the Gnome underground nuclear explosion, and located regional and local earthquakes. The B&R reduced travel-time curve obtained from a large untimed blast in a quarry west of Van Horn, Texas (VHB) is shown in Figure 9. Additional smaller blasts with waveforms and arrival time differences similar to those of the larger blast indicate all blasts are at the same location or within a few meters of each other (Nakamura, 1978). Therefore, data from several untimed blasts are used in this time distance plot. The first arrivals at all stations were impulsive and could be read to ± 0.05 sec. A later arrival that was consistently seen at stations EM and BP had an apparent velocity of 3.60 km/sec and is taken as the direct arrival. The ray path of the direct arrival at these two stations is mostly through sedimentary material. This phase could not be identified at the three remaining stations since the sedimentary layer is not continuous from the shot point to these stations. The shot time of the large blast was estimated from the intercept of the direct arrival time curve extrapolated to the shot point. Using these data a model of the upper crust for the B&R consists of three layers 3.56, 2.39, and 12.59 km thick, with velocities of 3.60, 4.93 and 6.11 km/sec, respectively, overlying a 6.6 km/sec layer. The 4.93 km/sec layer probably represents a volcanic section and the 6.11 km/sec layer may be the first indication of basement depth beneath the B&R. Following the first arrival at station EM by 2.3 sec there is a third arrival that could not be identified at the other four stations. This arrival can be interpreted as the reflection from the base of the 6.11 km/sec layer because its travel time agrees well with the calculated travel time for the model in Figure 8a. The reflected arrivals from the base of the 3.60 and

Figure 8: Summary of all crustal models mentioned in the text, (a) Van Horn Blast, Kermit and Snyder earthquakes, (b) Gnome and natural events around Kermit, (c) Chan, (1977), (d) Stewart and Pakiser, (1962). All models are described in the text. Dashed lines are inferred layer boundaries. (*) indicates a higher apparent velocity (see text for explanation).

Figure 9: Arrival time data used to derive the model in figure 8a recorded at stations MR, MOT, BP, and BR from a large explosion located at 104.959°W and 31.100°N . EM points were plotted on the same scale by using the time difference between EM and BP arrivals from smaller explosions at approximately the same source location.

Figure 9

4.93 km/sec layers at EM have approximately the same travel time as the first arrival from the respective layer, and therefore these phases could not be identified.

First arrivals from earthquakes about 190 km away near Kermit, Texas cross the UT/NASA array with an apparent velocity of 6.7 km/sec. The first arrival from the June 16, 1978 Snyder, Texas earthquake (Dumas, 1979) had an apparent velocity of 8.37 km/sec (epicentral distance \sim 420 km) and a secondary arrival had an apparent velocity of 6.7 km/sec. The 6.7 km/sec arrivals from the Kermit and Snyder areas are compatible with the 6.60 km/sec arrival from the VHB. Using the results from Figure 9 and the apparent velocities from the Kermit and Snyder earthquakes, we obtained a crustal model for the B&R that is summarized in Figure 8a. This model consists of four layers overlying a 8.37 km/sec mantle. The 8.37 km/sec velocity may be slightly higher than the actual mantle velocity beneath the B&R because at the epicentral distance of the Snyder earthquake the ray path penetrates deeper into the upper mantle thereby resulting in a higher apparent velocity. The data used to obtain this model were recorded entirely at the UT/NASA array.

To refine model 8a, an attempt was made to detect possible additional layers in the Marfa Basin using secondary arrivals observed from shallow earthquakes (<8 km). The epicentral distances for these events are between 20 and 56 km. The problem in using earthquakes is that they occur at various depths which will result in different travel times. However, we are interested only in the arrival time intervals between later arrivals in the seismic record and not the actual travel times. Since all the first arrivals were refracted from the 6.11 km/sec layer they were plotted on the same 6.11 km/sec curve regardless of depth. This has the effect of placing all foci on the same datum plane and, because the events were shallow,

time corrections for a change in focal depth may be neglected. Thus, later arrivals from various earthquakes refracted from a given horizon fall roughly along the same time-distance curve. Layer thicknesses can be calculated from the difference between intercept times of the arrival refracted from the 6.11 km/sec layer and any later arrival. The interval between intercept times are insensitive to focal depth provided both ray paths in question are refracted arrivals. This produces a crustal model in which revised epicenters may be obtained. This procedure is repeated until the R.M.S. residuals of the earthquakes no longer decrease. Using this procedure a 6.11 km/sec half-space gave the smallest residuals. This may be understood by considering that the seismograph stations are located on hard rock (mountainous areas) which may have a velocity of nearly 6.11 km/sec. Later arrivals may nevertheless define shallower layering. Figure 10a is the reduced travel time curve based on epicenters located in a 6.11 km/sec half-space.

For the Marfa basin events, the 6.11 km/sec arrival and a later arrival representing a deeper layer could be seen at all stations. However, there was little correlation between later phases on seismograms from opposite sides of the array. The scatter of these data (Figure 10a) suggests lateral inhomogeneities and discontinuous layering above the 6.11 km/sec layer. Therefore, the time distance curves in Figure 10a were drawn for ray paths to the western and eastern sides of the array. The model for the western side of the array consists of two layers above the 6.11 km/sec layer with velocities of 3.56 and 4.26 km/sec. The 3.56 km/sec arrival identified at stations MR and BR represents the direct wave through sedimentary material and the 4.26 km/sec arrival as being refracted from a deeper layer. The time interval between the intercepts of the 3.56 and 4.26 km/sec curves is 0.1

36
37

Figure 10a. Reduced travel time curve using travel times for local earthquakes based on a 6.11 km/sec half-space. The first arrivals at each distance (not shown) were constrained to fall on the 6.11 km/sec line. Closed triangles and circles indicate arrival times to stations on the western and eastern sides of the array, respectively. Open symbols indicate S-wave arrivals (Δ - west, \circ - east). Numbers at the right are the velocities associated with the respective time distance curve.

Figure 10a

sec. Assuming a point source this would place the events in the sedimentary section just above the 4.26 km/sec layer. Considering the ray paths shown diagrammatically in Figure 10b and the time interval between the intercepts of the 4.26 and 6.11 km/sec, indicate that the 4.26 km/sec layer is 1.9 km thick.

On the eastern side of the array only a 4.00 km/sec arrival was detected above the 6.11 km/sec layer. The 4.00 km/sec velocity is an intermediate velocity between 3.56 and 4.26 km/sec velocities observed on the western side of the basin. A velocity between 3.56 and 4.26 km/sec would be expected of the direct arrival if the source is located in the second layer. Using the intercept times of the 4.00 and 6.11 km/sec curves the epicenters are located 1.2 km above the 6.11 km/sec layer. However, the total thickness of the shallower layers can not be determined. The complexities in the seismograms for the two stations located in the Davis Mountains (BP and MOT), made an unbiased selection of later arrivals difficult. This suggests that the Davis Mountains are very heterogeneous.

The time interval between the intercepts of the 6.11 km/sec and 6.80 km/sec curves indicates the 6.11 km/sec layer is 10.2 km thick. This is in good agreement with the 12.6 km obtained from the VHB for the same layer considering the uncertainties associated with the use of earthquakes as a source for a refraction profile. If the differences between the two calculated depths are not due to observational errors then this suggests the Marfa Basin is dipping slightly (2.2°) towards the northwest. Figure 10b summarizes the crustal model for the Marfa Basin obtained from local earthquakes. Local events indicate non-homogeneous and discontinuous layering above the 6.11 km/sec layer and that the eastern side of the Valentine Fault is structurally higher

Figure 10b. Schematic crustal model (not drawn to scale) for the Marfa Basin derived from Figure 10a. Number at the right in each layer is the layer velocity and to the left is the layer thickness. There is no basis for estimating thickness of shallow layering in the east model. Abbreviations are: DM - Davis Mountains, SV - Sierra Vieja Mountains, and VF - Valentine Fault zone (see Seismicity section). Asterisk indicates average focal depth of local events with respect to the 6.11 km/sec layer. Refracted ray paths are indicated by small arrows, inverted triangle is a seismic station in the mountainous area.

Figure 10b

than the western side. Depth to each layer in Figure 10b is not given because the exact depth of the events are not known. However, layer thicknesses between refracting horizons are given along with velocities. Shurbet and Reeves (1977) estimated from gravity measurements that the sedimentary material in the Marfa Basin is at least 2.4 km thick.

In any case, we can obtain only limited information about such thin shallow layers using a large network and epicenters which are few and widely scattered. Thus, local earthquake data do not add sufficient information to refine the model of Figure 8a obtained from the VHB.

Travel-time data from the Gnome underground nuclear explosion (Romney et al., 1962) and well located natural events (GNE) recorded by many stations in the Great Plains and by two stations in the B&R, represent a regional travel-time curve (Figure 11) for west Texas. Interpreting these unreverse refraction data, we obtained a crustal model (Figure 8b) consisting of three layers totalling about 42 km, overlying an 8.13 km/sec mantle.

The B&R model in Figure 8a differs from the model derived by Chan (1977) (Figure 8c) from the Gnome underground nuclear explosion and local earthquakes (not located by the USGS). Chan's (1977) model consists of a layer 9 km thick with a velocity of 4.9 km/sec, overlying a 6.7 km/sec layer. The 6.0 km/sec layer was undetected by Chan, probably because of the smaller amount of data available to him. If he had been able to detect the 6.0 km/sec layer, then the calculated depth to his 6.7 km/sec layer would have been greater than shown in Figure 8c. Thus, the upper crust may be nearly the same in all models in Figure 8. This represents an almost uniform crustal

Figure 11: Travel-times for Gnome and natural events across west Texas. The Gnome data were recorded at temporary stations in west Texas (Romney et al. 1962) and the natural events were recorded at stations in the Kermit array (Keller, personal communications) and at the UT/NASA array. The travel-times indicate a three layer crust overlying a 8.13 km/sec half-space.

Figure 11

structure throughout T-PT.

Comparing the models shown in Figure 8, we find a 6.6 or 6.7 km/sec layer common to all models and a 6.0 km/sec layer common to three models. The west Texas models contrast notably with Stewart and Pakiser's New Mexico model by the absence of the 7.1 km/sec layer in the west Texas models. The addition of a 7.1 km/sec layer, which was unidentified in west Texas possibly because of sparse data would make those models nearly the same as the New Mexico model. On the other hand, west Texas models, as shown without the 7.1 km/sec layer in Figure 8 have shallower mantles than the New Mexico model. This alone could account for the differences in mantle depths between west Texas and New Mexico models.

SEISMICITY

Seismicity is low, yet detectable in the B&R and the northeastern part of Chihuahua, Mexico. Approximately 800 earthquakes with S-P intervals of less than 30 sec were detected and 10% of these were located. Hypocenter locations were obtained from P and S-wave arrivals, using the computer program HYPO 71 (Lee and Lahr, 1975) and the crustal model described in the previous section (Figure 8a). S-wave velocities were computed using a Poisson's ratio of 0.25. Station corrections (Table 2) were obtained by subtracting the theoretical arrival times of the large explosion (mentioned in the previous section) from the observed arrival times.

Whenever possible, arrival times from Carlsbad, New Mexico and/or the Kermit, Texas, network were also used in epicentral locations. Figure 12 shows that earthquakes in the B&R within 120 km of MOT and with magnitudes greater than 1.5 were within the locating capability of the UT/NASA network. Seismicity is best documented either inside or near the network in: 1) The area west to southwest of Van Horn; 2) The Marfa Basin (particular the eastern

Figure 12: Local magnitude vs. distance from MOT for small located events. Earthquakes with magnitudes of 1.5 could be located at least 120 km from MOT. The smallest event located by the network has a magnitude of 0.7.

Figure 13

side; and 3) The Texas-Mexico Border area. A few earthquakes have also been located in the Salt Basin Graben (SBG) and in the area north of the Black Gap.

Seismicity of Van Horn Area

The first instrumentally located earthquake ($m_b = 3.5$) in the Van Horn area occurred on March 6, 1962 at 31.2°N and 104.8°W (Sanford and Toppazada, 1974). Frequent quarry blasts west of Van Horn can be confused with natural seismicity. The quarries are located in an area characterized by numerous thrust, normal, and strike slip faults striking in a northwesterly direction (King, 1935). Since the dates and times of the blasts could not be obtained, all located events (natural and artificial) have been plotted in Figure . It is known that most of the blasts occur between 2130 and 2400 UT (1630-1900 local time). While the number of natural events is uncertain, events that occur outside of the 2130 to 2400 UT time interval are believed to be earthquakes. Whether these events were triggered by mining operations is still undetermined.

Southwest of Van Horn and east of station EM, a few events have been identified as earthquakes. These events may indicate an active northern branch of the Rim Rock Fault, which is locally the western boundary of the Marfa Basin.

Seismicity in the Marfa Basin

The area north of Valentine, Texas (Figure 13), has the greatest known seismic activity in the 3&R. Here seismic activity is concentrated at the end of a northwesterly striking diffuse zone (Figure 13). This zone is thought to be an active fault or faults and is referred to as the Valentine Fault zone. Surface faulting has not been found; however, it is likely that the thick alluvium in the Marfa Basin covers the fault scarp. The revised

epicenter of the 1931 Texas earthquake is located at 30.69°N and 104.57°W , at the northern end of this diffuse zone (Dumas et al., 1980).

One of the largest earthquakes in our list occurred on July 18, 1978 in the Valentine Fault zone. This earthquake was preceded by 18 foreshocks with magnitudes (m_L) between 0.7 and 2.1. The 'b' (LS) value of $0.65 \pm .48$ for the frequency-magnitude curve (Figure 14) is less than the b value for the regional seismicity (equation 4). Foreshock activity began on July 13, 1978 with a 1.7 (m_L) event and culminated on July 18, 1978 with the 2.6 (m_L) main shock (Figures 15a and 15b), following which no aftershocks were detected. Though this sequence was recorded only on the 1 mm/sec helicorder at station MOT, epicenters for these events were estimated to be at or near 30.5°N and 104.5°W by comparing seismograms and S-P times for these events to those of located events in the Marfa Basin. This places the sequence along the newly found Valentine Fault zone. The first motion at MOT for each event in this sequence was compressional.

The July 18, 1978 sequence was one of three ($m_L > 2.5$) that occurred in the Marfa Basin. Figures 16A, B, and C illustrate the time history of these foreshock sequences. Evison (1977) described sequences terminating in large earthquakes ($m_b > 4.9$) which follow a pattern similar to those of the Marfa Basin sequences. He identified four successive stages of: a) normal seismicity; b) precursor swarm; c) precursor gap; and d) main event, which are illustrated in Figure 16. Sekiya (1977) and Kodama and Bufe (1979) described a similar pattern for earthquakes in Japan ($m_b > 4.1$) and Central California ($3.5 < m_b < 5.7$), respectively. Aggarwal et al. (1975) noted variations in V_p/V_s ratios preceding a 2.5 (m_b) event at Blue Mountain Lake in New York. However, they made no mention of the temporal variations in foreshock activity preceding the main shock. To the author's knowledge this is

52

Figure 16: Temporal variation in seismicity preceding the main shocks (7) of four sequences. Each sequence is characterized by: a) normal background seismicity; b) precursory swarm; c) precursor gap; and d) main shock. Sequences A, B, and C occurred in the Marfa Basin and D is the Chihuahua 1980 sequence.

Figure 16

the first report of temporal variations in foreshock activity preceeding small shocks ($m_L < 3.7$). The low-level of background seismicity in the B&R makes small sequences more conspicuous than in more active areas where they may be masked by the higher background seismicity.

If we assume that earthquakes are completely independent from each other then the probability that r earthquake(s) will occur in time T is given by a Poisson's distribution (Sacuiu and Zorilescu, 1970)

$$P(r,T) = \frac{(\bar{N}T)^r e^{-\bar{N}T}}{r!}$$

where \bar{N} is the mean number of earthquakes per unit time. A property of the Poisson process is that the expected number of earthquakes in the time interval T is $\bar{N}T$. The mean number of earthquakes at MOT ($S-P < 8.5$) is 2.42 events/30 days. The minimum number of events in Figure 16 (part b) for a 3 day interval is 4 events. The expected number of events for a 3 day interval is .242 and the probability of a swarm of this size occurring within a radius of $S-P < 8.5$ sec of MOT is 1.12×10^{-4} . The probability of all events having the same epicenters is even lower. This suggests that based on a Poisson's distribution the events in Figure 16 are not spatially and temporally independent.

Evison (1977) also found a linear relationship between the magnitudes of the largest foreshock and the main event. In this study, no correlation was found between the magnitudes of the largest foreshock and main event. This is not unique for the small shocks observed here; Papozachos (1975) also found that for Greek earthquakes the magnitude of the main shock ($m_b > 4.7$) to be independent of the largest foreshock for events. It thus appears that the relationship between magnitudes of foreshocks and main shock

is dependent on the locale. There were however, six other events occurring in the Marfa Basin with local magnitudes greater than $2.5m_L$ that were not preceded by foreshock activity. Therefore, in terms of predicting the size of an earthquake for the B&R, the magnitude of the largest foreshock in the swarm (if a swarm does occur) will give no indication of the size of the main shock.

The seismicity on the western side of the Marfa Basin is lower than on the eastern side. Five events located south of station MR and BR are probably associated with the southern section of Rim Rock fault system (Figure 13).

Four events larger than 1.5 were located along the eastern boundary of the Salt Basin Graben (Figure 13). Figure 12 indicate that small events ($<1.5m_L$) on the western side of the SBG are below the location capabilities of the network. By comparing the total number of recorded earthquakes to the total number of located earthquakes, it is estimated that the number of earthquakes occurring in the SBG is 1.0 to 1.5 orders of magnitude higher than Figure 13 indicates.

Approximately 10 earthquakes with S-P times between 1 and 3 sec, and magnitudes less than 0.3 were detected only at station BR. These events are located between 8 and 25 km from station BR and may be associated with the Rim Rock fault system. Numerous small events with S-P times less than 2.5 sec (epicentral distance less than 20 km) were also detected at stations MOT and EM; however, because of the numerous faults in the Davis and Eagle Mountains, these events cannot be assigned to a particular fault.

Seismicity along the Texas-Mexico Border

The epicenters located in the study and plotted in Figure 13 for this area are accurate within 8 km, even though they lie outside the array. Most of them fall on a north-south line coinciding with the Sierra Pilares

and Pinosa Ranges. Pre-1975 events located by the U.S.G.S. appear to form a trend striking in a northeasterly direction, approximately perpendicular to the local structural trend. The locations of these pre-1975 events (Figure 13) may not be reliable, because of the sparse seismograph coverage in the area at the time.

One of the largest earthquakes ($3.6 m_L$) located instrumentally by the UT/NASA array occurred on February 18, 1978 approximately 50 km SSW of Van Horn, Texas and was followed by 23 aftershocks (1.3 to $2.9 m_L$) within two days. The main event was located at $105.10^\circ W$, $30.67^\circ N$, origin time was $14^h 22^m 22.10^s$. A few WWSSN stations recorded weak emergent P phases of the main shock and therefore, the hypocenter obtained from these readings had very large solution errors. The inability of the WWSSN network to detect and locate small events in northern Mexico implies that this region may be more seismically active than previously observed. The 'b' (LS) value of $0.59 \pm .36$ for the frequency-magnitude curve of the aftershock sequence (Figure 14b) is less than that for the regional seismicity (Figure 7). The flattening of the curve at lower magnitudes indicates that many of the smaller events of the sequence may have gone undetected.

Close examination of Figure 17 shows that a foreshock preceded the main shock by 12.5 sec. This is seen from the consistent time difference in the two P-arrivals (foreshock and main shock) at all stations, regardless of epicentral distance, which implies that phase 'a' (Figure 17) is associated with a different event and is not a later arrival of the same event. Figure 18 shows the close waveform similarities between seismograms for five events including the foreshock (*) at station EM. Similar seismograms are also found at the other recording stations as well. Figure 19 shows the ratios of S/P amplitudes are approximately constant for six events recorded at

Figure 17: Seismograms of the foreshock (P-arrival indicated by 'p') and the main shock (P-arrival indicated by 'a') for the February 18, 1978 Texas-Mexico sequence. The arrival times for all high speed playouts are delayed 40 sec.

The open circle represents the foreshock and the circles represent aftershocks. The S/P ratios remained constant for all events that did not exceed the dynamic range of the recorder.

Figure 19

65

station EM that did not exceed the dynamic range of the recorder. Thus, all the data suggest that the same focal mechanism is responsible for all events and that their epicenters must lie within a fraction of a wave length of each other. Reexamining the MOT helicorder records for the month preceding the main shock revealed no other foreshocks.

Another Chihuahua sequence began on June 22, 1980. It was located approximately 100 km south of the above mentioned sequence and 103 km southwest of BR, along the southern section of the Sierra Pinoza Range. The main shock ($3.8 m_L$) occurred on July 17, 1980 at $29.50^\circ N$ and $105.18^\circ W$, and the origin time was $3^h 41^m 31.3^s$. Unlike the previous Mexican sequence this one contained 10 foreshocks and 4 aftershocks. The temporal variation in seismicity preceding the main shock is similar to that of the Marfa Basin sequences (Figure 16D). The 'b' values for the foreshocks and aftershocks are $.51 \pm .38$ and 1.08 ± 1.7 , respectively (Figure 20). The large uncertainty in the 'b' value for the aftershocks is attributed to the small amount of data available and not to the quality of the data itself which was quite good. The higher 'b' value for aftershocks relative to the foreshocks has been noted by Rikitake (1976). The S/P amplitude ratios for 6 foreshocks (Figure 21) that did not exceed the dynamic range of the recorder and with readable P-arrivals are approximately constant with one exception ($P \sim 19.3$ mm). The latter suggests that the focal mechanism did not remain constant during the entire foreshock sequence.

Numerous Mexican events outside the area of Figure 13 were also recorded. The larger events had magnitudes between 3.0 and 3.5 (m_L) with clear P and S-wave arrivals. Location errors for these events are large due to the poor station distribution. None of these Mexican events were located or detected by local or regional WWSSN stations. Smaller events inside the area of Figure 13 had emergent P and S arrivals and could not be located.

Figure 21: S/P amplitude ratios for the Chihuahua, Mexico 1980 sequence. With the exception of the P-wave data point near 19 mm, S/P ratios are almost constant.

Figure 20

Figure 21

FOCAL MECHANISMS

Focal mechanisms were determined from fault-plane and composite fault-plane solutions (Figures 23, 24, and 25, Table 5) based on first motion data. Since the point at which the ray emerges from the focal sphere depends on the crustal model, inaccuracies of the model distort the fault-plane solution. Also, the quality of the fault-plane solution reflects the number and distribution of recording stations with respect to the hypocenter. The nodal plane selected as the fault-plane is the one that agrees with: 1) the strike of the local geology, and/or 2) the direction of the seismic trend. Because of the limited number of stations and the limited crustal information the solutions are only rough approximations of the focal mechanisms.

The Valentine Fault Zone

The composite first motion plot of impulsive first arrivals from 15 events located in the Valentine Fault Zone is shown in Figure 22. Attempts were made to plot the first arrivals by varying the hypocenter depths, since the uncertainty in hypocenter depths allows some flexibility in changing the angle at which the ray emerges from the focal sphere. Thus by increasing or decreasing the hypocenter depths, the data outside the inner circle of points will move inwards or outwards on radii of the focal sphere projections, respectively. Varying depths did not however, remove the inconsistencies in Figure 22. The composite fault-plane solution for the Valentine Fault zone (Figure 23) was obtained subjectively by small adjustments of the nodal planes of the 1931 Texas earthquake on Figure 22 (See Part I) and by removing earthquakes for which the number of inconsistent points

^aSolution of the 1931 earthquake^bEither nodal plane can be selected as the fault plane.

exceeds the number of consistent points with respect to a final adjusted solution. By this criterion a population of 10 events remained to fit to a single solution. It appears several other orientations are needed to fit all the data for the 5 events removed. The nodal planes of the 1931 earthquake and of the composite solution, which includes inconsistent points, strike in northwesterly and northeasterly directions. The strike of two northwesterly planes of the composite solution is approximately equal to that of the 1931 fault plane. However, the 1931 fault plane dips towards the NE (Figure 3), whereas the dip of the composite solution nodal planes range between 75°NE to 75°SW . Considering the available data, any nodal plane in the hatched area of Figure 23 that strikes in the NW direction could be selected as the fault-plane. The differences in the two solutions are attributed to the uncertainties in the crustal model used in this study.

Texas-Mexico Border Area

A composite first motion plot (Figure 24) combines data from four pre-1975 earthquakes located in the northeasterly striking zone that was mentioned in the seismicity section and the main shock of the February 18, 1978, sequence. Stations BP and MR had impulsive dilatational and compressional arrivals respectively, whereas MOT and EM had emergent compressional arrivals. The strike of the left hand nodal plane ranged between $\text{N } 12^{\circ}\text{E}$ and $\text{N } 64^{\circ}\text{E}$ with dips of 40°NW and 20°NW , respectively. The southeastward dipping nodal plane is poorly constrained by compressional and dilatational points in the eastern part of the projection and was drawn to coincide with the southwesterly line of earthquakes which provided the first motion data. Although numerous nodal planes are possible, especially

73

Figure 24: Composite fault-plane solution for the February 18, 1978 sequence and four events located in northern Mexico by the USGS (Earthquake File Tape). The first-motion data for the four pre-1975 events are from Tucson, Albuquerque, and Junction (USGS, micro-film library). See Figure 23 for explanation.

Figure 24

Figure 25

ORIGINAL PAGE IS
OF POOR QUALITY

nodal planes dipping towards the NW (hatched area indicates the range of acceptable solutions), the solid lines represent the most favorable solution. Regardless of the nodal plane chosen as the fault-plane, Figure 24 indicates northeasterly striking normal faulting. The fault-plane solution implies, at least locally, extension in a NW-SE direction. Except for the February 18, 1978 event, which lies at the intersection of two trends, none of the earthquakes located on the north-south line had clear impulsive first arrivals needed to obtain a fault-plane solution.

The Rim Rock Fault

Only one event located on the Rim Rock fault had sufficiently large P-wave amplitudes to determine a fault-plane solution (Figure 25). Although the solution is poorly constrained, it is consistent with the local geology. Figure 25 indicates a normal fault striking $N 10^{\circ}W$ and dipping $45^{\circ}W$ and the tension axis is oriented $S 85^{\circ}W$. Except for the Texas-Mexico solution, the other three solutions indicate the tension axes are oriented in a SW-NE direction.

TECTONICS

Fault-plane solutions of Figures 23, 24, and 25 (Table 5) indicate that strike-slip faulting and normal faulting are occurring in the eastern and western sides of the Marfa Basin, respectively. These solutions indicate that the B&R is undergoing extension in a west-southwest and east-northeast direction. In Chihuahua (Figure 26), the tension axis is oriented ⁿ ~~ia~~ a southeasterly-northwesterly direction. The strike of the tension axis in that area (Figure 26) is almost orthogonal to the strike of the tension axes for the previously mentioned solutions. Thus, it appears that all obtainable fault plane solutions represent tensional fracturing or crustal spreading, though the

Figure 26: Map of study area showing fault-plane solutions. Large arrow heads indicate the direction of the tension axes. The number by each solution corresponds to the figure numbered in Table 5. See Figure 13 for meaning of initials. Solid triangles indicate seismic stations.

Figure 26

direction of the tension axes differ in different parts of the region.

DISCUSSION AND CONCLUSIONS

The seismicity map in Figure 13 indicates that earthquakes in the B&R of Texas and Chihuahua, Mexico, occur along linear trends. Some of these trends appear to be associated with previously mapped faults which have been thought to be inactive, while others cannot be correlated with any visible structural features. In this section each seismic trend will be discussed separately as it relates to the immediate area in which it occurred. The data are insufficient to support a statement concerning the overall relation between the trends. At this time each trend appears to be independent of the others.

The seismic patterns in northern Chihuahua are oriented in a north-south and northeast-southwest direction. The seismic events, located by the UT/NASA array in the Chihuahua Trough, appear to be associated with the Sierra Pilares and Pinosa Ranges. Gries and Haenggi (1970), suggested that the tilting of the evaporites to the east during the time of Laramide deformation produced the thrust faults in the Chihuahua Trough. They also suggested that tilting was caused by broad arching from the center of the Chihuahua Trough and perhaps some minor basement deformation.

Gries and Haenggi (1970), showed that most of the tear faults in the Chihuahua Trough extend to a depth of less than 3.0 km. Therefore, these earthquakes are probably shallower than 3.0 km. The seismic activity we observe today along the Sierra Pilares and Pinosa Ranges may reflect continuing arching or basement deformation.

Figure 27 is a regional seismicity map for eastern Arizona, New Mexico, west Texas and northern Mexico for the time interval between 1960

and 1978. The seismicity associated with the Rio Grande Rift system in New Mexico appears to terminate at the United States/Mexico border. Activity is again observed in the Chihuahua Trough approximately 200 km southeast of where the Rio Grande Rift seismicity terminates and this appears to be the most active area in northern Mexico outside the Gulf of California. Figure 27 indicates no discernable seismic patterns for events occurring in the region, furthermore the events cannot be correlated with any structural surface features in the area.

The seismicity data from Mexico reveal little about a possible extension of the Rio Grande Rift system in Chihuahua. Only through detailed geophysical investigations in Mexico will this problem be solved.

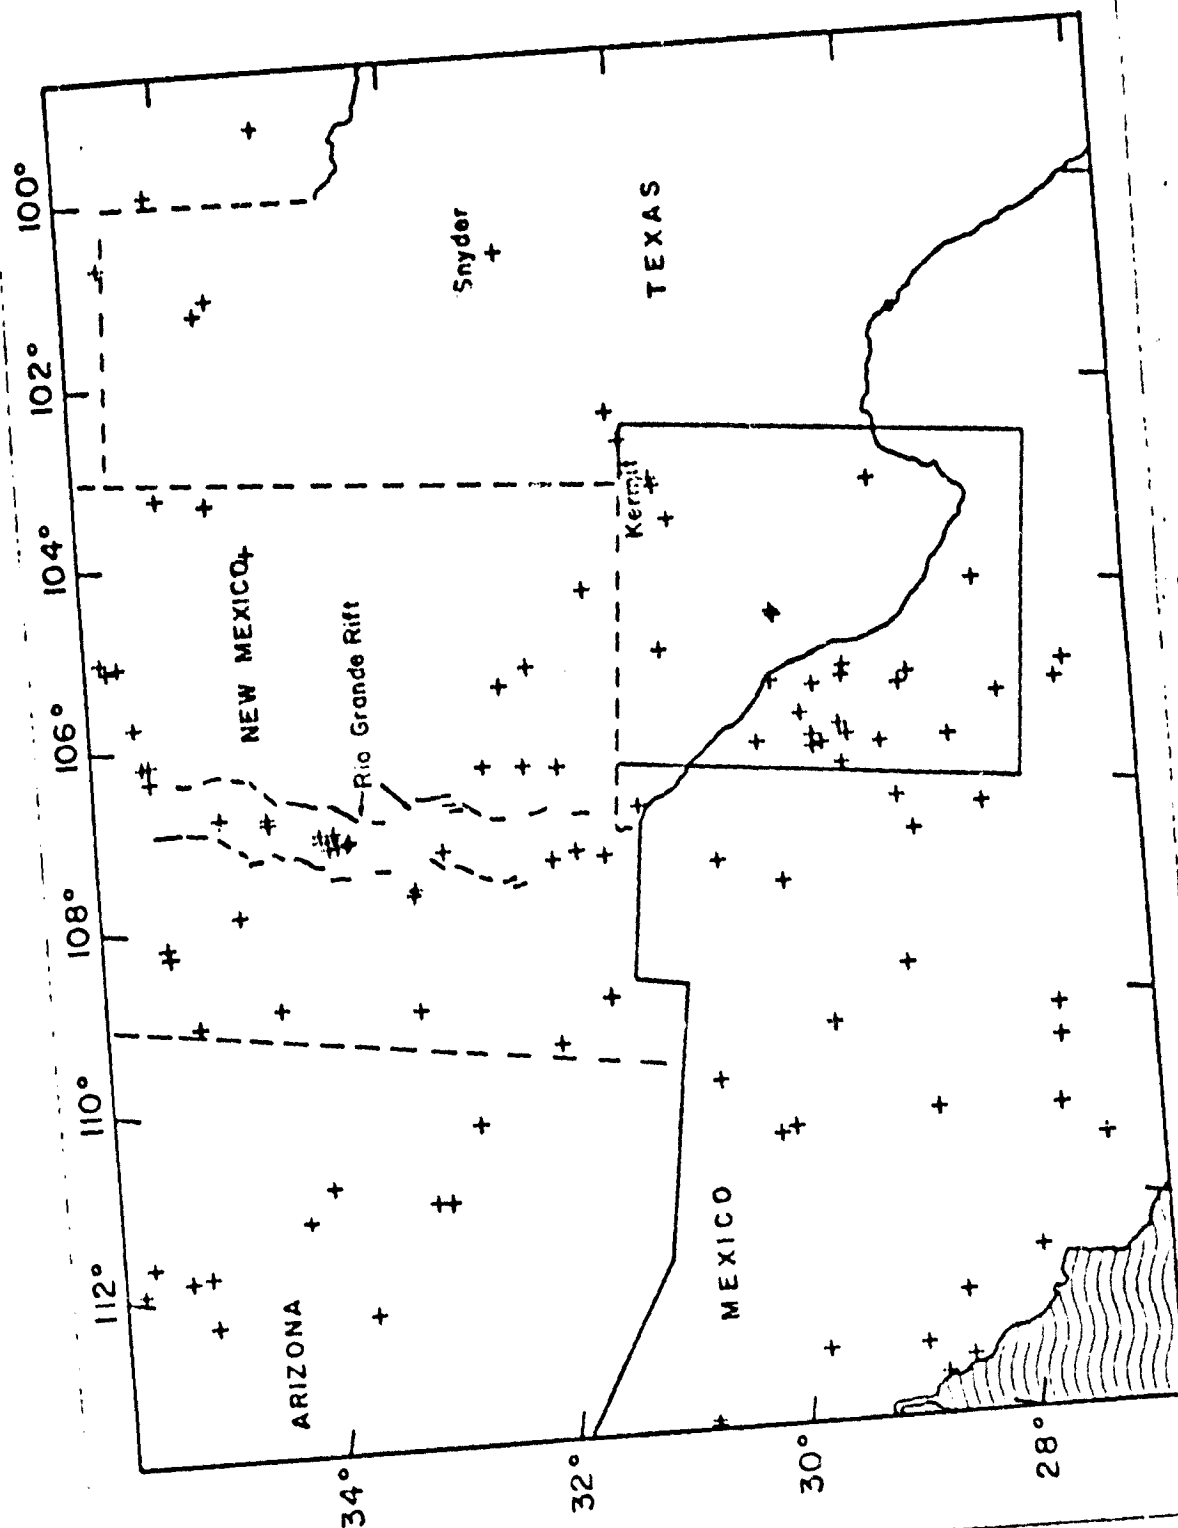

In discussing the structural and tectonic implications of the B&R we begin by examining the section north of Interstate 10. Seismicity in the northern section, as mentioned earlier, is observed on the eastern side of the SBG and the area west to southwest of Van Horn. We cannot report that the western side of the SBG north of Van Horn is inactive but that the network is incapable of locating any small events which may have occurred in the area. Because of the confusion about natural and artificial sources near Van Horn we could only speculate on possible tectonic implications of these events.

Repeated leveling traverses examined by Brown et al. (1973), indicate the Diablo Plateau (which forms the western boundary of the SBG) is presently undergoing uplifting at a constant rate of 5 ± 1 mm/yr, relative to the surrounding areas. This seems tectonically compatible with the SBG seismic activity reported in this study.

The SBG has the morphology of an active rift. However, Decker and Smithson (1975) reported normal heat flow (1 HFU) in the graben. Therefore,

Figure 27: Regional seismicity map (redrawn from Stover, 1977) for a portion of the southwestern United States and northern Mexico between 1960 and 1978. Epicenter locations are from the U.S.G.S., I.S.C., Sanford and Topozada, (1976), and events located during the study with magnitudes greater than 2.5 m_L . The rectangle indicates the area enclosed by Figure 13.

Figure 27

a feature of rifts such as the Rio Grande and East African rifts is lacking in the SBG.

South of the SBG (south of Interstate 10), the seismicity along the eastern side of the graben terminates. Activity is again observed immediately south of the Wylie Mountains in the eastern side of the Marfa Basin along the Valentine Fault zone. The importance of this active zone derives from the revised epicenter of the 1931 earthquake which lies at its northwestern end. Also, the zone coincides closely with part of the proposed eastern boundary of B&R faulting (Muehlberger, 1978). Thus, this zone may be the site of future earthquakes similar to the 1931 event.

Muehlberger's (1978) proposed eastern limit of B&R faulting extends from the Black Gap area, northwest through the Marfa Basin, past Valentine where it turns northwards and forms the eastern boundary of the SBG (See broken line Figure 13). However, field evidence of surface breakage is not visible in the alluvium in this section of the Marfa Basin. The northwest trending portion of the fault zone corresponds to the fault-plane solutions in Figure 23.

Hae-Roe (1975) and Muehlberger et al., (1978) have mapped a fault striking approximately N 15°W, and dipping 72°E just east of the Wylie Mountains (East Wylie Fault). This fault may continue southward to join the Valentine Fault zone in the area of greatest seismic activity, just north of Valentine. This area also coincides with the locus of maximum seismic intensity for the 1931 earthquake.

Based on the pattern of Quaternary fault scarps, Muehlberger et al., (1978) suggest the B&R of west Texas is undergoing extension in a S 80°W direction. This is in agreement with the orientation of maximum extension from the seismic data in this study and by Dumas et al., (1980).

83

The new findings about the 1931 earthquake (Dumas et al., 1980) and the nature of active seismicity in the eastern side of the Marfa Basin suggest the possibility of forecasting/predicting an earthquake from short term precursor (foreshocks). In the 1931 earthquake sequence and in several small earthquake sequences reported above, the main shocks were preceded by foreshocks. We have an eyewitness report that foreshocks of the 1931 earthquake were felt just hours before the main shock. Thus it seems probable that imperceptible foreshocks occurred for days, weeks, or even months before the main event. Contemporary reports do not provide a detailed history of foreshocks activity for the 1931 event, but data on temporal behavior of the Marfa Basin foreshocks sequences derived from Figure 16 may be combined with the precursory time data taken from Evison, (1977) and Ohtake et al., (1977) as in Figure 28. Here the precursor time measured from the start of the anomalous foreshock activity to the main event is plotted against the magnitude of the main shock. The anomalous foreshock period from Evison (1977) and Figure 16 begins with the precursor swarm (Figure 16, part b), whereas the anomalous foreshock period from Ohtake et al., (1977) begins with a decline in activity before the main shock. The data in Figure 28 are approximated by the line

$$\log T = 0.56M - 0.60 \quad (8)$$

This investigation indicates the B&R is a very complex area. On a broad scale, the B&R consists of four crustal layers, having seismic velocities of 3.60, 4.93, 6.11 and 6.60 km/sec, overlying a possible 8.37 km/sec mantle velocity. Except for the uncertainty about the presence of a 7.1 km/sec layer in the B&R, we are unable to identify a gross difference in layering between the Great Plains and the B&R in west Texas. Thus, it appears that the B&R crust is simply an area of Great Plains crust disrupted by volcanism and young faults, some presently active. The data support

86

Muehlberger's (1978) proposed eastern boundary of Basin and Range faulting which coincides with an active fault zone in the eastern side of the Marfa Basin. The 1931 earthquake occurred along this zone and only a few of our localized epicenters are east of this line. It appears that this active trend consists of a possible spreading axis in the SBG which bends sharply into a right lateral transform fault along the active Valentine trend.

Appendix

Instrumental locations for earthquakes in the Basin and Range province of Texas and the adjacent area of Mexico. Locations were determined by the use of HYPO-71 (Lee and Lahr, 1975). The column headings are as follows:

Date - Year/month/day

Origin Time - This is universal time (UT) and is given to the nearest tenth of a second.

Lat N - Latitude (North) given to the nearest hundredth of a minute.

Long W - Longitude (West) given to the nearest hundredth of a minute.

Depth - Depth is given in km. (*) indicates depth is constrained to 4 km.

Mag - The magnitudes listed are local magnitudes determined from signal durations and are obtained from the following formula

$$m_L = 2 - \log \tau - 2.51$$

MOT, BP, EM, MR, and BR - These are the UT/NASA stations used in the location scheme. The numbers in the columns indicate the number of readings per station used to locate each event. One (1) indicates P-wave arrival only and two (2) indicate both P and S wave arrivals were used.

Dmin - Distance to nearest station in km.

Gap - Largest azimuthal separation in degrees between stations.

RMS - Root mean square error of time residuals in sec.

ERH - Estimated standard error of the epicenter in km. If ERH is blank this means ERH cannot be computed because of insufficient data.

ERZ - Estimated standard error of the focal depth. If ERZ is blank this means that ERZ cannot be computed because either the focal depth was fixed in the solution or because of insufficient data.

Q - Quality of the hypocenter solution. This measure is intended to indicate the general reliability of the solution (Lee and Lahr, 1975).

Comments - The three (3) letter codes indicate additional station(s) used in the epicenter locations.

VITA

David B. Dumas was born [REDACTED] the second son of Mr. and Mrs. Dumas. After completing his work at Central High School, Galveston, Texas, in 1965, he entered Texas Southern University, Houston, Texas. He then entered active duty with the Navy in 1967, serving two years in and out of Vietnam. He returned to Texas Southern University in 1969 and received the degree of Bachelor of Science with a major in physics in May 1973. He then entered the Graduate School of Rice University, Houston, Texas. He was awarded the degree of Masters of Arts for Geophysics in May 1976. While working towards the degree of Doctor of Philosophy from the University of Texas at Dallas he has author or co-authored the following articles:

Geophysical Investigation of Salt at the University of Texas Geophysical Laboratory, Salt Dome Symposium, Louisiana State University, 1976 (Coauthor).

Seismicity in and around west Texas, Presented at the Conference of Cenozoic Geology of the Trans-Pecos Volcanic Field, 1979.

Active Seismic Focus near Snyder, Texas, Bull. Seis. Soc. Am., 1979.

The Seismicity of the Gulf of Mexico, EOS, vol. 61, no. 17, 1980 (Coauthor).

A reevaluation of the August 16, 1931 Texas Earthquake, Bull. Seis. Soc. Am., 1980 (Coauthor)

Seismicity in the Basin and Range province of Texas and north-eastern Chihuahua, Mexico, New Mexico Geological Society Guidebook, 31st Field Conference, Trans-Pecos Texas, 1980.

Summary of local and regional earthquakes (S-P < 30 sec) recorded at the University of Texas/National Aeronautics and Space Administration (UT/NASA) seismic network, UT Marine Science Institute, Contribution No. 465, 1981.
